Abstract

In this note, we describe a probabilistic attack on public key cryptosystems based on the word/conjugacy problems for finitely presented groups of the type proposed recently by Anshel, Anshel and Goldfeld. In such a scheme, one makes use of the property that in the given group the word problem has a polynomial time solution, while the conjugacy problem has no known polynomial solution. An example is the braid group from topology in which the word problem is solvable in polynomial time while the only known solutions to the conjugacy problem are exponential. The attack in this paper is based on having a canonical representative of each string relative to which a length function may be computed. Hence the term *length attack*. Such canonical representatives are known to exist for the braid group.

1.   Introduction

Recently, a novel approach to public key encryption based on the algorithmic difficulty of solving the word and conjugacy problems for finitely presented groups has been proposed in [1, 2, 20, 21]. The method is based on having a canonical minimal length form for words in a given finitely presented group, which can be computed rather rapidly, and in which there is no corresponding fast solution for the conjugacy problem. A key example is the braid group. In this note, we will indicate a possible probabilistic attack on such a system, using the length function on the set of conjugates defining the public key. Note that since each word has a canonical representative, the length function is well-defined and for the braid group can be computed in polynomial time in the word length according to the results in [6]. The attack may be relevant to more general types of string rewriting cryptosystems, and so we give some of the relevant background. Thus this note will also have a tutorial flavor.

The contents of this paper are as follows. In Section 2, we make some general remarks are rewriting systems, and the notion of "length" of a word. In Section 3, we define the Artin and Coxeter groups. In Section 4, we discuss the classical word and conjugacy problems for finitely presented groups. In Section 5, the braid cryptosystem of [1] is described. In Section 6, we give the length attack for possibly compromising such a cryptosystem, and finally in Section 7 we draw some general conclusions, and directions for further research for group rewriting based encryption systems.

2. Background on Monoid and Group Based Rewriting Systems

In this section, we review some of the relevant concepts from group theory for rewriting based encryption. We work in this section over a monoid, but similar remarks hold for group based rewriting systems as well.

Let k be an arbitrary field, and $S = \{a_1, \ldots, a_n\}$ a finite set. Let S^* be the finite monoid generated by S, that is,

$$S^* = \{a_{\sigma(1)}^{i_1} \cdots a_{\sigma(n)}^{i_n}\}.$$

Elements of S^* are called *words*. We then define the *free algebra* generated by S to be

$$A = k[S^*] = k <S> = \{\sum_{\sigma \in \Sigma_n} k_{i_1 \ldots i_n} a_{\sigma(1)}^{i_1} \cdots a_{\sigma(n)}^{i_n}\},$$

where Σ_n denotes the symmetric group on n letters.

We are now ready to define precisely the key notion of *rewriting system*. Let $R \subset S^* \times S^*$. We call R the set of replacement rules. Many times the pair $(u, v) \in R$ is denoted by $u \to v$. The idea is that when the word u appears inside a larger word, we replace it with v. More precisely, for any $x, y \in S^*$, we write

$$xuy \to xvy,$$

and say that the word xuy has been *re-written* or *reduced* to xuy. x is *irreducible* or *normal* if it cannot be rewritten.

We will still need a few more concepts. We say that the *rewriting system* (S, T) is *terminating* if there is no infinite chain $x \to x_1 \to x_2 \to \cdots$ of re-writings. We then say that the partial ordering $x \geq y$ defined by $x \to \cdots \to y$ is *well-founded*. R is *confluent* if a word x which can be re-written in two different ways y_1 and y_2, the re-writings y_1 and y_2 can be re-written to a common word z.

Note that if R is terminating, confluence means that there exists a unique irreducible word, x_{red} representing each element of the monoid presented by the re-writing system. Such a system is called *complete*. Given a word $x \in S^*$, we define the *length of x* or $\ell(x)$, to be the number of generators in x_{red}.

Remark:
In the case of groups, the basic outline just given is valid. A key example of a group in which one can assign a length function is the braid group via the results in [6]. This is the basis of the cryptosystem proposed in [1].

3. Artin and Coxeter Groups

In this section, we review some of the pertinent background on Artin and Coxeter groups. An excellence reference for this material in [5], especially for the braid groups.

Let G be a group. For $a, b \in G$ we define

$$<ab>^q := aba\ldots, \quad \text{product with } q \text{ factors.}$$

For example,

$$<ab>^3 := aba, \ <ab>^4 := abab, \ <ba>^5 := babab.$$

An *Artin group* is a group G which admits a set of generators $\{a_i\}_{i \in I}$ with I a totally ordered index set, and with relations of the form

$$<a_i a_j>^{m_{ij}} = <a_j a_i>^{m_{ji}},$$

for any $i, j \in I$ and with m_{ij} non-negative integers. The matrix $M := [m_{ij}]_{i,j \in I}$ is called the *Coxeter matrix*.

The *braid group*, B_n, is defined by taking the indexing set $I := \{1, \ldots, n\}$, and

$$
\begin{aligned}
m_{ij} &= 2 \quad \text{for } |i - j| > 1, \\
m_{i,i+1} &= m_{i+1,i} = 3.
\end{aligned}
$$

Thus the *braid group* B_n is a special case of an Artin group defined by the generators $\sigma_1, \ldots, \sigma_n$, with the relations

$$
\begin{aligned}
\sigma_i \sigma_j &= \sigma_j \sigma_i \quad |i - j| > 1, \; i, j \in I, \\
\sigma_i \sigma_{i+1} \sigma_i &= \sigma_{i+1} \sigma_i \sigma_{i+1}.
\end{aligned}
$$

Given an Artin group G with Coxeter matrix $M := [m_{ij}]_{i,j \in I}$ the associated *Coxeter group* is defined by adding the relations $a_i^2 = 1$, for $i \in I$. One can easily show them that a Coxeter group is equivalently defined by the relations

$$
(a_i a_j)^{m_{ij}} = 1, \quad i, j \in I, \text{ with } m_{ii} = 2.
$$

Artin groups and their associated Coxeter groups have some nice properties which could make them quite useful in potential rewriting based systems as we will now see.

4. Word and Conjugacy Problems for Finitely Presented Groups

Let

$$
G = < s_1, s_2, \cdots, s_n : r_1, \cdots, r_k >
$$

be a finitely presented group. Let U be the free monoid generated by s_i and s_i^{-1}. Then the *word problem* is given two strings (words), $u, v \in U$, decide if $u = v$ in G. The *conjugacy problem* is to decide if there exists $a \in G$ such that $u = ava^{-1}$, i.e., u and v are conjugates.

It is well-known that both these problems are algorithmically unsolvable for general finitely presented groups. However, for some very important groups they are solvable, e.g., for Artin groups with finite Coxeter groups. In fact, Brieskorn and Saito [8] give an explicit solution to the word and conjugacy problems for this class of groups. Their algorithm runs in exponential time however. See also [13, 14] and the references therein for some recent results on the word and conjugacy problems for Coxeter groups.

In some recent work, Birman-Ko-Lee [6] show that for the braid group, the word problem is solvable in polynomial time (in fact, it is quadratic in the word length). Given the results just described, it has been conjectured that the techniques of [6] are extendable to Artin groups with finite Coxeter groups. For another solution to this problem see [11].

At this point, there is no known polynomial time algorithm known for the conjugacy problem, as originally posed by Artin [3], for the braid group with $n \geq 6$ strands; see [6]. It seems that it is the possible complexity of this form of the conjugacy problem which is the basis of the claim of security made by the authors of the braid cryptosystem in [1]. (The original conjugacy problem posed by Artin is a decision problem. Given $x, y \in B_n$, is there an a such that $x = a^{-1}xa$? In the proposed cryptosystems, the public and private keys are known to be conjugates, so these systems are not based on such a decision problem.)

For the braid group itself, little work has been accomplished on the lower and average bounds of the conjugacy search problem for known conjugates (as in [21]) or a system of known conjugates (as in [2]). There are no proofs that the conjugacy problem is hard all the time. The motivation to do any of this work has only occurred recently because these cryptosystems have been proposed. Some of this work includes a brief look at the probabilities of colored Burau representation [17], and other work attempting to demonstrate the average complexity of the conjugacy problem [23] using a set measurement techniques for infinite groups [7]. Other work has begun on calculating the normalizer set to solve the conjugacy problem [15] (but this does not help solve the crypto-problem because it assumes a known conjugator exists.)

It is important to note that there are some important linear representations of the braid group namely, the Burau, the colored Burau and the Lawrence-Krammer. In [2], it is suggested that the colored Burau representation made be used to quickly solve the word problem. The Burau representation was originally formulated to prove that the braid group was linear, but it now is known to have a non-trivial kernel and as such, cannot be used to solve the general conjugacy problem. Finally, using a more general representation due to Lawrence-Krammer, it has been proven that the braid group is indeed linear [4]. This allows linear algebraic methods to be used now in studying the word and conjugacy problems, and possibly could lead to yet another attack on braid cryptosystems.

Finally, note that if one can find a unique irreducible word from which one can derive a length function, then one can give a natural distance between words in a given group G. Indeed, let α, β, γ denote words relative to a finite presentation of the group G. Let ℓ denote the length function which we assume exists. Then we define the *distance d* between the words α, β as

$$d_G(\alpha, \beta) := \ell(\alpha\beta^{-1}).$$

It is trivial to check that d_G is a distance function function between words. See also [13]. We will see that this is the case for the braid group via the results of Birman-Ko-Lee [6].

5. Braid Cryptosystem

In some very interesting recent work, Anshel et al. [1, 2] propose a new twist to rewriting systems for public key encryption. We will first state their approach over a general group. We should first note however that the use of the word and conjugacy problems for public-key cryptosystems is not new. An early reference is [25].

The general idea is as follows: Alice (A) and Bob (B) have as their public keys subgroups of a given group G,

$$S_A = <s_1, \ldots, s_n>, \quad <t_1, \ldots t_m> .$$

A chooses a secret element $a \in S_A$ and B chooses a secret element $b \in S_B$. A transmits the set of elements $a^{-1}t_1 a, \ldots, a^{-1}t_m a$ and B transmits the set of elements $b^{-1}s_1 b, \ldots, b^{-1}s_n b$. (The elements are rewritten is some fashion before transmission.)

Now suppose that

$$a = s_{\sigma(1)}^{i_1} \cdots s_{\sigma(n)}^{i_n}.$$

Then note that

$$
\begin{aligned}
b^{-1}ab &= b^{-1}s_{\sigma(1)}^{i_1} \cdots s_{\sigma(n)}^{i_n} b \\
&= b^{-1}s_{\sigma(1)}^{i_1} b \, b^{-1}s_{\sigma(2)}^{i_2} b \cdots b^{-1} s_{\sigma(n)}^{i_n} b \\
&= (b^{-1}s_{\sigma(1)}b)^{i_1} \cdots (b^{-1}s_{\sigma(n)}b)^{i_n}.
\end{aligned}
$$

(The conjugate of the product of two elements is the product of the conjugates.) Thus A can compute $b^{-1}ab$, and similarly B can compute $a^{-1}ba$. The common key then is

$$a^{-1}b^{-1}ab = [a, b],$$

the commutator of the two secret elements.

Note that since the two users have the common key written in different forms, in order to extract the message, it must be reduced to an identical group element. For the braid group, this can be accomplished by reducing the commutator to the Birman-Ko-Lee canonical form [6], colored Burau [2] or Dehornoy [1].

The braid group is particularly attractive for this protocol since one has a quadratic time solution for the word problem, and the only known solution to the conjugacy problem is exponential.

Remark:

The key properties that underlie this cryptosystem are having a group in which the word problem is easy to solve (and in fact each word has a canonical form) and in which the conjugacy problem is difficult (at least via known techniques). The canonical form is important as well since it allows a simple method for the extraction of the common key.

5.1. Another Braid Cryptosystem

Another possible cryptosystem based on the word and conjugacy problems in the braid group has been proposed in [20, 21]. In this case, the authors propose the following scheme: Consider the braid group B_{n+m} on $n + m$ braids. One considers two subgroups: LB_n generated by $\sigma_1, \ldots, \sigma_{n-1}$ and RB_m generated by $\sigma_{n+1}, \ldots \sigma_{n+m-1}$. Note that given $a \in LB_n$ and $b \in RB_m$, $ab = ba$. This is essential for their scheme.

The protocol for creating a common key then works as follows: The public key is a pair of integers (n, m), and braid $x \in B_{n+m}$. Alice choose a secret element $a \in LB_n$ and sends axa^{-1} to Bob. Bob chooses a secret element $b \in RB_m$, and sends bxb^{-1} to Alice. Alice can compute $a(bxb^{-1})a^{-1}$ and Bob can compute $b(axa^{-1})b^{-1}$. Since a and b commute this is the common key. Being able to solve the Generalized Conjugacy Problem would be enough to break this system. It is not known if the converse is true.

Remark:
It is an interesting open question to see if the length attack proposed below may be suitably modified to be relevant to the protocol in [20]. It may be also be of interest to consider some the strong convergent game-theoretic techniques in [13, 14] to study this protocol as well as that in [1].

6. The Length Attack

In this section, we describe the length attack on word/conjugacy based encryption systems of the type proposed in [1] in which one can associate a canonical representative, and therefore a length function ℓ of the type described above. For concreteness, we focus on the braid group here which has a canonical length function as noted above. *We should note that the arguments of this section are speculative, and certainly not mathematically rigorous.*

Research on the length of random words has been done in the mathematical physics community where braid group has been valuable in studying certain physical phenomena [9, 12, 24]. Recall that a symmetric random walk on a free group Γ_n with n generators is a cross product of a nonsymmetric N-step random walk on a half–line $\mathbb{Z}^+$ and a layer over $N \in \mathbb{Z}^+$ giving a set of all words of length N with the uniform distribution (see [24] for the details). The transition probabilities in a base are:

$$N \to \begin{cases} N + 1 \text{ with the probability } \frac{2n-1}{2n} \\ \\ N - 1 \text{ with the probability } \frac{1}{2n} \end{cases}$$

It is easy to show then that the expectation of a word's length after N steps is

$$N \frac{n - 1}{n}$$

and hence the drift is

$$\frac{n - 1}{n}.$$

In [24], the authors show that while the statistical properties of random walks (Markov chains) on locally free and braid groups are not the same as uniform statistics on these groups, nevertheless the statistical

characteristics stabilize as the number of generators n grows. From this fact, for large n (see [24], Theorem 11) given two generic words $x, y \in B_n$, the length of xy will be approximately $\ell(x) + \ell(y)$. (The genericity is important here. For example, if $x = y^{-1}$ then $\ell(xy) = 0$.) This does give some statistical backing to the length attack which we are about to formulate.

Given $x \in B_n$, we say that y is a *reducing with respect to x* (or a *reducing element* if x is understood), if

$$\ell(y^{-1}xy) < \ell(x).$$

The remainder of this discussion will be a way of using substantial reducing strings in a *length attack*, and calculating an upper bound for the actual difficulty of this attack. It is important to emphasize that the ability of removing large reducing elements is not a general solution to the braid conjugacy problem. It is a specific attack on word/conjugates encryption systems of the type defined [1]. Indeed, for such cryptosystems one has the some key information about the secret elements, namely, the *factors are known and their number bounded.*

Let

$$a \in S_A = < s_1, \ldots, s_n >,$$

be the secret element. Recall that in the above protocol, $a^{-1}t_r a$ and t_r $(r = 1, \ldots m)$ are publicly given. We also assume that the factors s_i have lengths large relative to a. For given r, set

$$u_r = a^{-1}t_r a.$$

Then the idea is to compute

$$\ell(s_j^{\pm 1} u_r s_j^{\mp 1}),$$

repeatedly. If s_j is a reducing string with respect to u_r, then one has found a correct factor of a with a certain probability which will depend on the lengths $\ell(s_i)$ for $i = 1, \ldots, n$. The key is that the canonical lengths $\ell(s_i)$ should be large. In this case, there is the greatest probability of a reducing string being formed which can be used to glean information about a.

We can estimate the workload in carrying out such a procedure. Without loss of generality we can assume that a is made up of n distinct factors combined in d ways. If the length of the s_i is large, then one join a small number of these factors together to create a substantial reducing string. If we include the inverses of the generators, we should consider $2n$ factors. Let us call the number of factors necessary to make a reducing string k. Thus we can create $(2n)^k$ reducing factors to try.

By trying all reducing elements, a pattern that there are certain factors which annihilate better than others should be observed. One can do this on a single public conjugate in $(2n)^k$ operations. This pattern can be significantly reinforced by repeating this n times on each public conjugate $a t_r a^{-1}$. Combining all the steps above brings us to $n(2n)^k$ operations.

Relative to the lengths $\ell(s_i)$ of the generators s_i (and the specific group chosen), we conjecture that in a number of cases this will be sufficiently reliable to removing a given s_i, so that backtracking will not be necessary. We can now do this dn times bringing the total to $dn(2n)^k$ operations.

This is polynomial to the number of different factors, and linear to the number of factors in the public keys. This is the basis of the length attack.

Another demonstration of this idea is trivial. If one sets $k = d$ then the first of the dn passes will solve the system in the expected exponential time $2n^k$ steps. This is simply an enumeration of all possible values of a. If one sets $k = 1$ then, if individual factors are not significant, this attack will not work. If there is a value of $k < d$ that works, this attack significantly reduces the strength of the result. Once this attack is valid, then lengthening the private key only linearly increases the time to solution.

Depending on the values chosen for the cryptosystem in [1], k may need to be longer than the actual word a, as has been suggested in [2][1]. Yet another potential problem is that if the factors are simple, other attacks such as those proposed in [19] may be effective.

---

[1]This attack was known to the authors before that paper was written

In some sense, the length attack is reminiscent of the "smoothness" attack for the Diffie-Hellman public key exchange system based on the discrete logarithm [22]. In this case, the protocol may be vulnerable when all of the prime factors of $q - 1$ (where the base field for the discrete logarithm has q elements) are small. (Such a number is called *smooth*.)

7.   Conclusions

We have made a computation which indicates that a length attack on a conjugacy/word problem cryptosystem of the type defined in [1] has difficulty bounded above by $dn(2n)^k$. Given this conjecture, the only exponential aspect is the number of factors necessary to form a reliable reducing string. To make this secure, k needs to be 100 or larger.

In addition, as described, this attack does not use many tricks that one can use in order to speed up this length algorithm by several orders of magnitude. These include randomized and/or genetic algorithms which lead to more probabilistic solutions.

The bottom line is that the length attack forces one to take generators of not too long canonical length. Dorian Goldfeld reports that experimental evidence suggests that if each of the generators $s_1, \ldots, s_n$ is of length < 10 in the Artin generators, then this may foil the attack. All of this still must be tested.

Finally, it is important to note that this attack does not solve the general conjugacy problem for the braid group. Indeed, in this case the factors of a are known and bounded. In the general conjugacy problem, the number of possible factors of a is infinite. Consequently, the the conjugacy problem seems to be much harder and not amenable to this technique. The key exchange of the type proposed in [1] requires the factors be known and communicated, and give the attacker far more information than is known to the general conjugacy problem.
